PROPOSED BULK GRAIN STORAGE INSTALLATION LONG PLAINS RAILWAY YARD, HUNDRED DUBLIN

DUBLIN 1-MILE SHEET (ZONE 6, NO. 815), NE AND SE QUADRANTS

INTRODUCTION

It is proposed to construct a wheat storage silo toward the northern end of the Long Plains Railway yard which is about 40 miles north from Adelaide. Two percussion test bores were drilled at the request of Mr. J.A. Corbett, Senior Engineer, S.A. Co-operative Bulk Handling Ltd., for the purpose of testing the foundation conditions.

In Bore No. 1 sealed tube samples were taken at five foot intervals down to a depth of 50 ft. At all other depths down to the bettem of the bore at 90 ft., epen tube samples were taken and extruded into plastic envelopes. Open tube samples only were taken from Bore No. 2 which was finished at 25 ft.

The number of blows per foot of penetration were recorded during both open and sealed tube sampling in the two bores. Pocket penetrometer readings were measured in the cohesive sample material.

The location of the bores and the general geology of the area are shown on plans accompanying this report. Records of the number of blows per foot of penetration and pecket penetrometer readings are included in the descriptive geological logs of the samples in an appendix. This information is also shown on a cross section drawn through the bores. Also in the appendix are descriptive logs of a 583 ft. bore, 2 miles south-west from the site. The positions of seismic shot hole bores are shown on the plan.

TOPOGRAPHY

The area is part of the plains of the St. Vincent
Basin. The site is situated on the Ridley Plains, a low-lying
area with small surface irregularities and vague surface drainage.
The presence of gravel beds at shallow depth in parts of the
low-lying areas suggests the presence of former river courses.
The boundaries of the low-lying areas appear to be, in part,
small eresional terraces. Slightly higher ground occurs to the
morth where a system of fixed acclian dunc ridges is present.

GEOLOGY

A sheet kunker has apparently developed on the eld dune and riverine topographies fixing the forms of an eld land surface.

An erosional cycle has removed the kunkar sheet from some of the low-lying areas, including the sile site position. This erosion did not remove the kunkar sheet from the higher, fixed dune areas.

The original sand of the dume ridges has been blown from the ridge crests and redistributed as thin sand sheets in the interdunal areas and on portions of the Ridley Plains. Some post kunkar thin alluvial material is also present on parts of the low-lying areas.

The sequence of deeper sediments is given by a 583 feet deep water here about two and a half miles south-west from the site (Hd. Dublin, Sect. 97) which penetrated terrestrial clays with sands and gravels down to marine limestone at 134 ft.

Interbedded limestone and fessiliferous marks were found to continue to 311 feet. Sands and clays then continue to 376 feet where ancient Palaeozoic to Proterozoic sediments were penetrated.

A log of this bore is given in the appendix. Other bores in the district but outside of the area of the accompanying plan have shown that extensive lignitic materials are frequently present at depth.

Samples from the two foundation bores at the site show that a limey silty sandy clay soil everlies red-brown and light, slightly greenish grey clays. The clays are generally sandy and silty and some thin sand horizons are present.

The occurrence of near surface gravels and Quaternary erosional features suggest the possibility that an everlying cover of material has been removed from the red-brown and grey clays.

FOUNDATION CONDITIONS

The test drilling at the site has shown that generally friable limey silty and sandy clay occurs down to about five or six feet. The underlying cohesive clays are all stiff to very stiff and are damp to the touch. Pecket penetrometer readings in these clays are consistently off scale suggesting fairly high compressive strengths and the possibility of preconsolidation.

There is a higher sand and silt content from 16 to 25 feet and the material is semi cohesive and crumbly to friable.

This material, however, is very compact and required from 10 to 30 blows per foot of penetration.

Water was not struck in the foundation testing. No authenticated water table data was available close to the site.

CONCLUSIONS AND RECOMMENDATIONS

The upper five to six feet of silty sandy clay with lime may be subject to significant settlement and is not considered to be as satisfactory a foundation material as the underlying very stiff cohesive clays which continue to a depth of about sixteen feet. The thickness of this very stiff clay may be sufficient to spread the leadings ever the more friable silty and

sandy clays which extend down to about 25 feet. Below 25 feet the material is again cohesive and stiff and has a penetration rate of ever 20 blows per foot.

Soils mechanics tests may assist in determining a suitable depth for the footings which would be consistent with the structural requirements.
