THE COMPILATION OF COAL BOREHOLE DATA FOR COMPUTER PROCESSING: SUMMARY OF AN INDUSTRY METHOD

INTRODUCTION

The author worked as well site geologist for a large exploration company during 1977. This report summarises the operational methods employed, and describes a system of encoding borehole data for computer processing. The report may serve as a basis for possible Departmental establishment of a similar data-processing system.

Exploratory and delineation drilling was carried out on a brown coal deposit which locally was upgraded by thermal metamorphism to a semi-anthracite. Seven coal seams were developed, averaging fifty metres in total thickness. Individual seams were laterally extensive and contained numerous tonstein bands and silicified lenses.

All coal borehole data were compiled and filed using the COGEO computer system (summarised in Figure 1).

Personnel were based at a well-appointed field camp including offices and coreshed located within the lease holdings.

DRILLING OPERATIONS AND INITIAL CORE HANDLING

Drill rigs used were three Longyear 38's equipped with triple-valve Bean pumps, a combination designed specifically for core drilling: few holes were rotary-drilled. Operations continued on a 24-hr basis with two twelve-hour shifts. Drilling ceased for twelve hours every Sunday to facilitate machinery maintenance and drilling crews' rotation.

Core was cut in three-metre lengths where possible, following standard diamond-coring practices. Although the drilling company was contracted to recover a minimum of 90% of the coal core cut, otherwise being required to redrill at their cost, 80% recovery often was accepted (as determined by the well site geologist). All core was extruded onto split PVC pipe halves with perforations at regular intervals to enable drainage. The pipe halves were 3.5 m in length, in groups of three, each group being supported by a strong wooden tray.

A geologist's assistant was available at the rig site. His duties were to remove excess drilling mud from the coal, mark the base of driller's runs with enscribed wooden blocks, wrap fresh samples for analysis (total moisture, sodium and geotechnical) as directed, cover all core trays with canvas, and add water when appropriate to prevent core desiccation.

For rotary-drilled holes the assistant collected cuttings samples at three-metre intervals.

WELL SITE GEOLOGY

A well site geologist was assigned to each drilling rig in operation. For exploratory holes (which were always cored) the geologist was required to remain on site for the duration of the day shift. Core was not logged at night. For delineation holes the geologist was required on site only to log the accumulated core from each drilling shift. Although the geologist remained on site if stratigraphic problems were apparent, he otherwise returned to the project site office to compile borehole data.

For the occasional rotary-drilled hole the geologist would only visit the site each day to check progress.

Field core descriptions were made on a standard borehole log sheet (Figure 2) using COGEO (computerised geology) nomenclature (abbreviated in Appendix I). The following geological and geotechnical parameters were recorded:

- 1. drillers depth
- 2. unit thickness
- 3. R.Q.D. (recovered quality determination: the length of core recovered in sticks longer than 10 cm).
- 4. % lithology, qualifiers, and colour
- 5. weathering
- 6. permeability
- 7. plasticity
- 8. durability, resistance to abrasion
- 9. strength
- 10. bedding
- 11. jointing
- 12. sedimentary-tectonic structure
- 13. accessory minerals
- 14. sample number
- 15. remarks

All coal core was wrapped in plastic, water was added, the plastic sealed and the core boxed. Core for sodium analysis initially was wrapped in aluminium foil, bound with Scotch tape and then wrapped in plastic, but it was discovered that the foil contaminated the sample. Thereafter samples were wrapped first in plastic, bound with cellotape, then secondly in aluminium foil, bound with tape then immersed in molten wax inside a suitable length of PVC tubing to ensure that the sample remained undisturbed. A representative 10% of non-coal core also was boxed. The remaining 90% of non-coal core was discarded.

Assistants placed core into wooden core boxes 1.1 m long with five internal divisions. Foam rubber commonly was used to pack on top of the core, to minimise the risk of damage during transportation to the coreshed.

GEOPHYSICAL BOREHOLE LOGGING

All boreholes were logged by BPB Industries Ltd. Geophysical logs used were:-

- 1. gamma-long spacing density-caliper 1:200 scale general log
- 2. point resistivity, neutron-neutron 1:200 scale general log
- 3. gamma 1:20 scale detail log
- 4. long spacing density 1:20 scale detail log
- 5. high resolution density 1:20 scale detail log (resolution 20 cm)
- 6. caliper 1:20 scale detail log
- 7. resistivity and/or focused electric 1:20 scale detail log.

 The detail logs Nos. 3-7 inclusive were run over the coal seam intervals only. All log data were recorded both digitally and as analogues, and logs were presented to the client as sepias after preparation at the field office. General 1:200 scale field-copy logs also were available at the well site.

COAL SAMPLING

Boxed coal core was laid sequentially onto the coreshed tables. The recovered core was correlated with the geophysical logs. Such units as silicified coal, tonstein bands and resin bands were excellent markers enabling the core to be "pegged" against the logs: intervals of core loss commonly could be determined with an accuracy of ± 1 cm. Many transitional lithologic boundaries too subtle to identify macroscopically at the well site (eg. carbonaceous clay to clayey coal) could be identified by careful comparison with logs at the core shed.

This procedure also provided a check on field - recorded lithologic thickness.

Thus, coal core selected for bulk density, total moisture and sodium analysis was accurately located relative to the geophysical logs; this is critical if computer crossplots of core data are to be used correctly for calibrating geophysical logs and subsequently determining coal ash contents in rotary-drilled holes.

Intervals of homogeneous lithology or transitional lithology between two homogeneous lithologies were sampled. Generally coal sample intervals were restricted to a maximum length of two metres.

Bulk density was determined for all total-moisture-analysis samples and tonstein samples (if preserved as a stick). Samples were weighed; wholly crushed; a portion sent to the laboratory for analysis (chemical, ash fusion, crucible, swelling index, volatiles etc); and the remainder kept as a reserve.

Core for sodium analysis was specially prepared. Only core available in sticks of approximately 60 cm lengths was selected. Each stick was separated into four samples - 10 cm from either end; the central core portion; and an outer layer from the entire stick comprising about one third of the core radius. This method was followed to determine whether the sodium content was inherent, or due to contamination from drilling muds. In addition, at some locations three separate holes were drilled using respectively water, CMC or bentonite as drilling mud, to determine relative mud-contamination effects.

A sample-interval log was constructed on the Gamma Detail Log. A reference depth for each coal seam was ruled on the Gamma-LSD-Caliper 1:200 General Reference Log. Subsequently, coal core interval depths were read from the gamma logs.

A Sample Submission Sheet (Figure 3) was compiled for each borehole. One copy remained on file at the core shed and the original was sent with the coal samples to the laboratory.

The core recovery percentage from a given interval could be roughly checked by dividing the gross weight of the coal sample by its represented thickness and comparing it with the known average weight per centimetre of core for coal from that area. This check proved very useful, especially when chemical analysis conflicted with geophysical log characteristics, e.g. relatively high ash-content from analysis but low gamma count from logs. Such conflicts commonly occurred for samples immediately above and below clay bands. If the core weight/length was greater than the known average, it then was assumed that the core was "telescoped" or that a clay band may have been included in the sample. The sample interval then was adjusted appropriately after rechecking all data.

After sampling, the residual non-coal core was telescoped, reboxed and stacked in a core library.

BOREHOLE DATA PRESENTATION

All borehole data were compiled on standard sheets, termed "blocks". These were used for both cored and rotary-drilled holes.

CL Geology Block

Non-coal core was correlated with the Gamma-LSD-Caliper 1:200 General Log and Resistivity, Neutron-Neutron 1:200 log, and using the former as the depth standard, field core descriptions were transferred to the CL Geology Block (Figure 4A,4B). The Gamma Detail Log provided the depth standard for coal-seam intervals, descriptions for which were similarly entered.

The CL Block is basically an expanded borehole field log. Drilling data also could be recorded - weight on bit, flush returns, rpm, penetration rate, mud weight, mud temperature and resistivity - but appropriate columns are not shown on Figure 4A. Other columns on that enclosure relate to:

- entry number eg. line 0001, 0002 etc.
- interval, eg. depth recorded in metres
- stratigraphic unit names, eg. group, formation
- unit, eg. seam 2
- subunit, eg. tonstein 3
- information type, coded: 1 cuttings only
 - 2 logs only
 - 3 core only
 - 4 sidewall core only
 - 5 logs & core
 - 6 logs & cuttings
 - 7 logs & sidewall core
 - 8 driller only

Other Blocks

Additional data were presented on appropriate survey, chemical analysis and geotechnical analysis code sheets.

<u>Lithologs</u>

A generalised percentage litholog was drawn in a 10 cm wide column on the Gamma-LSD-Caliper 1:200 General Log.

COMPUTER PROCESSING APPLICATIONS

All data were filed on computer tape. The computer was programmed to:

1) adjust all analyses for core loss, calculate an interval weighted average, and ultimately calculate a reconstituted bulk coal seam analysis.

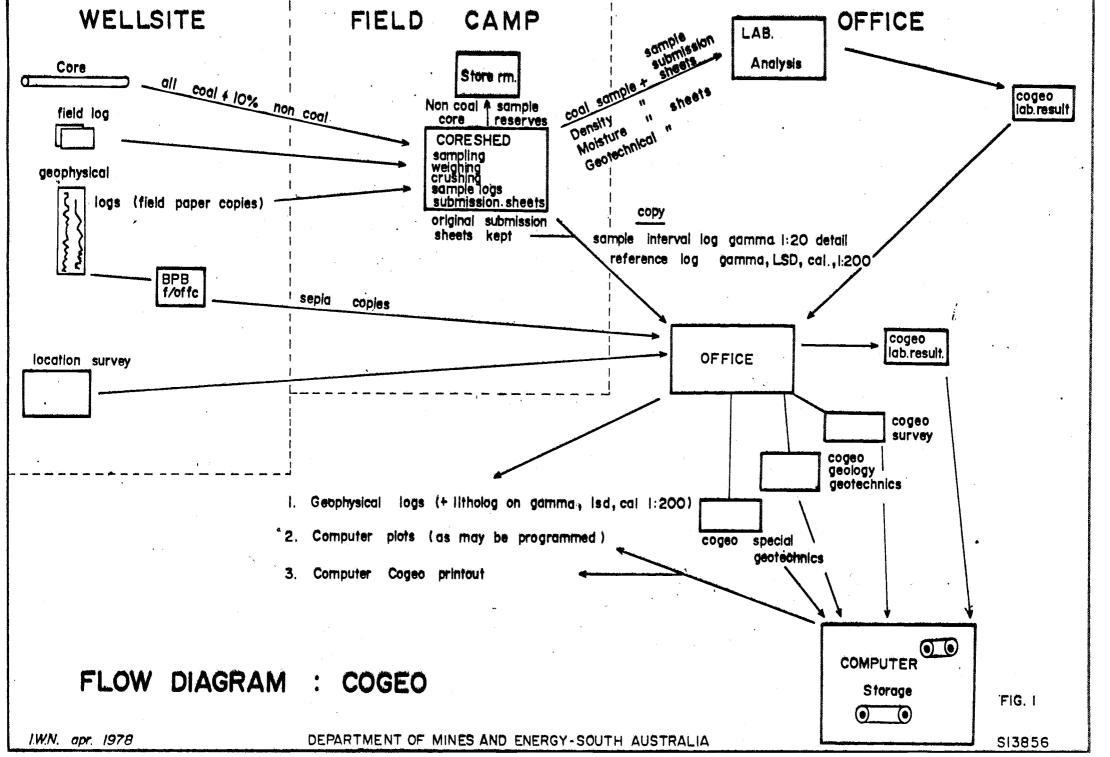

- 2) prepare plots of contourable data eg. seam thickness, depth to roof, depth to floor, interseam thickness.
- 3) calculate coal reserves
- 4) calculate overburden/coal ratios
- 5) calculate ash determination from geophysical borehole data crossplots.

Computer applications to coal exploration and delineation are further discussed in Peeters and Kempton (1977).

WEATHERING

SØ Soil discoloured, changed to soil. Original fabric destroyed. WC Completely weathered - discoloured, changed to soil-original fabric remains.

WH Highly weathered, discoloured, discontinuous discoloured surfaces, alteration penetrates deeply. Fabric altered near discolouration surfaces.

WE Mod. weathered, discoloured discontinuities have discoloured surfaces, alteration penetrates slightly. Intact rock weaker than rock.

WX Slightly weathered may be discoloured, discontinuities have discoloured surfaces.

FH Fresh, no discolouration, max strength. BT Burnt, scoria, naturally coked coal.

STRENGTH

Rock

- R7 extremely strong requires many hammer blows to break.
- R6 very strong requires several hammer blows to break intact material.
- R5 strong requires hammer blow to break hand held sample.
- R4 moderately strong can't be cut with knife. Pick indents to 0.5 cm.
- R3 moderately weak difficult to obtain shallow cuts Pick indents deeply.
- R2 weak knife cuts deeply crumbles under pick blows.
- R1 very weak brittle or tough, difficult to break in hand.

COHESIVE SOIL

- C4 Stiff cannot be moulded with fingers, but nail indents
- C3 Firm moulded by strong fingers pressure
- C2 Soft easily moulded with fingers
- C1 V. soft exudes between fingers when squeezed

NON COHESIVE SOIL

- G4 weakly cemented lumps of soil can be abraded with thumbs
- C3 compact non cemented requires pick for excavation
- G2 loose could be excavated with a spade
- G1 v. loose hand penetrates easily

PLASTICITY

- LE Lean silty and/or non sticky when wet, doesn't roll easily into 3 mm diam. threads when moist. Marked dilatancy, low dry strength.
- IN Intermediate. Slightly sticky clays. Rolls into 3 mm dia. threads when moist. Some shrinkage in drying.
- FA Fatty very sticky clays. Usually swelling. Rolls easily into 3 mm threads when moist. High dry strength, considerable shrinkage in drying.
