27 CURRIE STREET ... ADDRESS LONGREACH ...

CHIEF CLERK
21 JUL 1971
DEPT. OF MINES
ADELAIDE

LSD/AW

13th July, 1971

The Director of Mines,
Box 38,
Rundle Street P.O.,
Adelaide.S.A.5000

Dear Sir,

S.M.L. 551 RADIUM HILL S.A.

Attached are our Technical Report and Exploration Expenditure Summary for S.M.L.551 for the period 11th March to 11th June 1971

Yours faithfully,
LONGREACH METALS N.L.

for L.S.DENHOLM
Exploration Manager

Encls.

1632

TECHNICAL REPORT FOR PERIOD 11th MARCH TO 11th JUNE 1971

The following is a summary report of activities carried out in the S.M.L. area during the three month period ending 11th June,1971:-

1) MUTOOROO RIDGE PROSPECT

The diamond drilling programme which was commenced during January,1971, continued during the quarter. Three holes, (M5, M6,M7) totalling 2215'7" were completed. A fourth hole, M8, is still in progress (see Plan 4.1b for locations).

Drill holes M2, M3, M4 (completed in previous quarter) M5, M7 and M8 (in progress) have been drilled to test coincident induced polarization and geochemical anomalies located between 172E and 188E during the previous period. All holes completed to date have intersected patchy, low grade, copper mineralization.

DDH M6, which was designed to test an I.P.anomaly on line 172N, did not intersect any significant copper mineralization. Minor pyrite, with associated magnetite, is thought to have caused the I.P. anomaly.

The assay results for M2, M3, M4, M5 and M6 are summarized in Table I. Silver values of up to 44 ppm have been obtained but these occur over narrow intervals only and are not economically significant.

2) Radiometric and Magnetic Anomalies

The results of the auger drilling programme conducted during the previous quarter were not encouraging. (see report for SML 274 period 1st March 1970 to 1st March 1971 for details). No further work will be carried out over these anomalies.

Future Exploration

Further exploration will be proposed subject to the results of DDH M8.

Plans

The following are attached:-

a) Fig 1 Geological Locality Map showing location of Diamond Drill Holes.

b) Fig 2 DDH M2, 3, 4.

c) Fig 3 DDH M5

d) Fig 4 DDH M6

e) Fig 5 DDH M7

f) Drill Log Sheets for DDH M2 - 7

SPECIAL MINING LEASE 551

RADIUM HILL - SOUTH AUSTRALIA

Technical Report for the Period
11th March, 1971 to 11th
September, 1971.

A. EDWARDS,
Resident Geologist.

LIST OF FIGURES

C O N T E N T S

SUMMARY

0053

Exploration in the S.M.L. area during the period was confined to the Ridge Prospect. Four drill holes, totalling 3015', were completed. A number of narrow steeply dipping lenses of low grade copper mineralization were intersected. Further drilling will be required to test the south westerly extension of this mineralization.

INTRODUCTION

1.1 Tenancy

The S.M.L. area was initially granted to Longreach Metals No Liability on March 1st, 1969 as S.M.L. 274. Tenure of the area was retained for a further six months in March 1971 subject to the expenditure of $30,000 on exploration. The area contains 799 square miles.

1.2 Location and Access

The area is located on the 1:250000 scale Olary sheet between latitudes 32°24' and 32°50' and longtitudes 140°30' and 141°00'.

Access to the area is by way of a formed road, which leaves the main Adelaide to Broken Hill road some 4 miles west of Cockburn. The formed road terminates at the Mutooroo Homestead which lies in the north east corner of the S.M.L. area.

Access within the area is by station tracks.

1.3 Topography

The area is located on the northern margin of the Murray Basin. As a result the southern two thirds of the area is devoid of substantial relief. The country consists of open salt bush and bluebush plains, with eucalypt and acacia scrub in the south and west.

The northern portion of the area generally shows more relief. The gently undulating saltbush and bluebush plains are broken by occasional ridges of quartzite, tillite and B.I.F. The Maldorky Hills, which lie in the north west of the area form the highest point in the S.M.L.

The area is drained by a series of ephemeral streams. These drain to the south of the area where they gradually die out.

2. PREVIOUS WORK

2.1

The northern margin of the area where it laps onto the Ballara 1 mile Sheet has been mapped by Sprigg (1951) and Campana and King (1958).

The whole of the area has since been re-mapped as part of the South Australian Mines Departments regional mapping programme of the Olary 1:250,000 Sheet. Mapping of the Mutooroo 1 mile Sheet was by A.F. Williams, R.A. Callen re-mapped the Ballara sheet.

An investigation of mineral leases 3038, 3039 and 3040 was conducted by N. Hevin during 1956. These leases were located about 6 miles south of the Mutooroo Homestead.

2.2 Geophysics

Aerial magnetometer surveys were flown over the area by the South Australian Mines Department and the Bureau of Mineral Resources between 1953 and 1955.

3. REGIONAL GEOLOGY

3.1 Archean

The oldest rocks in the area are the granitic gneisses and schists of the Willyama complex. These rocks outcrop in the north east of the S.M.L. area, and are inferred in the extreme north of the area from aeromagnetics (see Figure 2). Associated with the gneisses in the Mutooroo Homestead area are a number of north easterly trending amphibolite dykes.

The Willyama blocks are bounded by north easterly and north westerly trending shears, which are parallel with the Macdonald shear zone and the Anabama-Redan fault zone respectively. These are the major basement lineations in the area.

3.2 The Adelaide System

The rocks of the Adelaide System occupy a large triangular area north of the Anabama-Redan fault zone, which trends almost diagonally across the area. These rocks are complexly folded in the zone of adjustment surrounding the Macdonald shear zone, where it intersects the nose of the north easterly trending Wadnaminga Anticline. The effects of this are well illustrated on Figure 2.

Movements on the Anabama-Redan fault zone have resulted in some complex folding and in inliers of older material being faulted in.

The main stratigraphic units present in the area are:-

(a) Callana Beds

A small, highly deformed wedge of volcanics and sediments occurs within a north easterly trending ridge some 7 miles south of the Mutooroo Homestead. The rock types recognized include trachytes, sodic rhyolites, chlortic schists and quartz muscovite schists.

(b) Burra Group

The Burra group is represented by interbedded conglomerates, coarse grained arkoses and siltstones, overlain by grey phyllitic siltstones and dolomites. South Australian Mines Department mapping has correlated the arkosic units with the Rhynie sandstone.

(c) The Yudnamutna Sub Group.

The Burra Group sediments are overlain by tillites, with some interbedded hematite lenses and siltstones, quartzites and dolomites. This unit overlies the Willyama complex unconformably in the north east of the S.M.L. area.

3.3 Recent Deposits

Much of the area is covered by a veneer of sand and silt with well developed calcrete horizons.

3.4 Igneous Rocks

(a) Anabama Granite

From the aeromagnetic survey it was inferred that the Anabama Granite extends into the far west of the S.M.L. area. Although the granite does not outcrop, its presence has been confirmed by auger drilling .

(b) Pegmatites

A number of small dykes and pods of pegmatite have been found intruding the Lower Burra Group sediments. The rock consists of pink plagioclase and quartz with coarse grained ilmenite as a common accessory mineral.

(c) Diorite

A course grained altered diorite occuring in a narrow dyke has been located within the trachytes mentioned above. The rock in principally composed of oligoclase/andesine leucoxenized opaques and chlorite epidote pseudomorphs after homblende. Minor malachite staining was also observed.

4. SUMMARY OF EXPLORATION BY LONGREACH METALS N.L. PRIOR TO MARCH 1971.

An airbourne magnetometer and spectrometer survey was carried out over the S.M.L. area during 1969. This survey revealed sixteen local magnetic anomalies and two areas of anomalous radioactivity.

The magnetic anomalies were located on the ground by traversing with a ground magnetometer. Programs of soil sampling or auger drilling were carried out in conjunction with detailed ground magnetics and geological mapping. The results from this work were not encouraging and no further work was undertaken.

The eastern area of anomalous radioactivity was examined in some detail on the ground. Initial ground exploration included geological mapping, spectrometer surveys and a percussion drilling program of four holes. Gamma ray logs and radon gas determinations run on the percussion holes were encouraging and resulted in the drilling of a 525' diamond drill hole No. DDHM1. No economic mineralization was encountered, although anomalous U_3O_8 values were recorded.

The western radiometric anomaly was tested by an auger drilling program. Results were not encouraging.

Ground investigations located two areas of copper mineralization known as the Ridge and Lyndock Prospects. Ground exploration consisted of an integrated program of detailed geological mapping, soil sampling and ground magnetics followed by an induced polarization survey over selected areas.

Coincident I.P. and geochemical anomalies were delineated over a strike length of some 2000' on the Ridge Prospect. A diamond drilling program was commenced during January 1971 to test these anomalies. Details of this work were reported in March 1971.

5. EXPLORATION DURING THE PERIOD MARCH 11TH, 1971 to SEPTEMBER 11TH, 1971.

RIDGE PROSPECT

5.1 Geology

The area was mapped on a scale of 400' = 1" during the previous year. The principal area of interest, known as the drill site was mapped on a scale of 100' = 1".

5.1.1 Rock types

(a) Arkosic Conglomerates and Sandstones.

The conglomerates consist of angular quartzite pebbles with minor shale fragments in a matrix of chlorite and sericite schist. Heavy mineral bands are common. The sandstones, which are compositionally equivalent, range from course to fine grained types.

(b) Quartz Muscovite Schists

These rocks are fine grained with quartz mullions and blebs prominent in some localities.

(c) Chlorite Biotite Schists

Over much of the area these rocks were not differentiated. In general they occur as grey green friable schists. Sedimentary laminations are retained in some areas. In the drill site area, two types of schist could be differentiated.

(i) Meta Volcanics

These are dark grey schists, commonly vesicular with quartz and carbonate infilling the vesicles. The original rock was thought to have been a sodic trachyte.

(ii) Chlorite biotite schists derived from silts and tuffs. These are are mainly greenish black schists with grey interbeds and occasional lenses of quartzitic pebbles and grits.

(d) Rhyolites and Schists

The rhyolite is a fine grained blocky siliceous rock consisting of pink and grey phases which define intricately folded laminations. The grey phase which is more prominent appears vesicular in some localities. When sheared, the rhyolite forms a grey and white spotted schist.

5.1.2 Structure

The rock mass has suffered intense shear slip folding which resulted in a major horizontal anticlinal structure trending sub parallel to the length of the ridge. This folding was accompanied by transposition. Numerous small folds occur on the limbs of the major structure.

A second episode of shear slip folding transverse to the first episode has occured in the drill site area. The secondary folding has been attributed to a strong horizontal movement to the southwest on the Amabama-Redan Fault zone, which lies to the immediate south of the prospect area.

5.1.3 Mineralization

The sulphide assemblage encountered during drilling at the Ridge Prospect includes pyrite, bornite, chalcopyrite and chalcocite. The surface expression of the mineralization is mainly in the form of malachite with minor chalcocite.

The chalcopyrite mineralization appears to be associated with magnetite rich bands within rocks of muscovite chlorite metamorphic grade. The metamorphism is accompanied by increased amounts of accessory potash felspar.

The bornite is commonly intergrown with chalcocite, and is often intimately associated with crystals of ilmenite. The ilmenite sometimes contains traces of rutile. In a number of cases the sulphides were found to be replacing the oxides. Ilmenite and rutile were identified from a number of the cores sectioned and were not always found to be associated with copper mineralization.

The mineralization tends to occur in lenses or pods up to 32' thick, and dipping to the N.W. at 70°–75°.

Concentrations of copper mineralization occur in the vicinity of quartz muscovite schist/chlorite-biotite-schist contacts, within lenses of pebbly and gritty chloritic schist, and around fault zones.

The controls for the primary mineralization have been obscured by the repeated metamorphism. Some lithological and possibly structural control can be inferred from the distribution of the secondary mineralisation.

5.2 Diamond Drilling

The diamond drilling program commenced during January 1971 was continued. Four holes, (DDH M5, M6, M7 and M8) totalling 3075' were completed during the period. The locations of these holes are shown on Figure (3).

All core was logged, and selected intersections were split and assayed. Assays were performed by Geochemical and Mineralogical Laboratories Pty. Ltd. of Sydney.

The significant assays from all holes drilled are shown in Table I. The geological logs are summarized in Figures 4 to 8 .

Holes M5 and M7 were drilled to test the mineralization encountered in holes M2, M3 and M4.

M6 was designed to test an I.P. anomaly on line 172E.

DDH M8 was designed to test any possible extension of the mineralization encountered in DDH M7.

5.3 Conclusions

1. A series of steeply dipping lenses of low grade secondary copper mineralization have been intersected by drilling between lines 180E and 188E. This mineralization should extend at least as far as 172E.
2. From the results of M4 and M8, it is possible that the mineralization is limited in depth between 180E and 188E. DDH M7 indicates that the mineralization may plunge to the SW.

3. The controls of the primary mineralization are at present not fully understood due to the repeated metamorphism. Some lithological and structural control can be inferred from the distribution of the secondary mineralization.

4. Any possible extension of the mineralization to the S.W. could be tested by drilling on line 172E. It is significant that an I.P. anomaly was delineated on line 164, along strike from the known mineralization.

6. RECOMMENDATIONS

6.1 The area surrounding the Ridge Prospect should be retained, together with all extensions along strike.

6.2 The S.M.L. with the exception of the Ridge Prospect, shows little potential and should be relinquished.

6.3 Further drilling should be undertaken to test the south west extensions of the mineralization in the vicinity of 172E.

LEGEND

- Metatrachyte
- Pebbly Chloritic Schists
- Gritty Chloritic Schists
- Undiff. Chloritic Schists
- Quartz Mica Schists
- Quartz veins
- Shear

For location of drill holes see plan no.4-1(b)

LOCALITY PLAN

LEGEND

- Undifferentiated chlorite-biotite schist
- Chlorite-biotite schist, metamorphosed volcanics
- Chlorite-biotite schist, metamorphosed sediments
- Quartz Muscovite schist, metamorphosed quartzitic and arkosic conglomerate and sandstone
- Rhyolite
- Grey and white quartz-muscovite schist, metamorphosed rhyolite
- Diorite dyke
- Quartz
- Foliation
- Cleavage
- Joint
- Fault
- Shaft
- Pit
- Trench
- Malachite stain
- Soil sample grid point
